Kinematic Artifacts in Prestack Depth Migration

Christiaan C. Stolk * and William W. Symes †

ABSTRACT

Strong refraction of waves in the migration velocity model introduces kinematic artifacts - coherent reflectivity not corresponding to actual reflectors - into the image volumes produced by prestack depth migration applied to individual data bins. This pathology occurs for all common binning strategies, including common source, common offset, and common scattering angle. Since the artifacts move out with bin parameter, their effect on the final stacked image is minimal, provided that the migration velocity model is kinematically correct. However common image gathers exhibit energetic events with substantial residual moveout, even when the migration velocity model is kinematically correct.

INTRODUCTION

Unstacked migrated image volumes are the raw material of migration velocity analysis. Migration velocities are assessed and estimated by means of the semblance principle: if the velocity is correct, then images formed from different data bins within the unstacked data volume should be the same, at least with respect to phase. Thus image gathers (migrated traces sharing a common surface location), displayed in depth vs. bin parameter, should appear flat. Velocity analysis adjusts migration velocity iteratively to flatten image gathers, the flatness being assessed either directly through visual inspection, or indirectly through velocity spectrum peak location, or both. (?, ?, ?, ?).

In principle, any binning scheme can serve as the basis for a velocity analysis method, so long as independent images can be formed from each bin - that is, so long as the migration operator can be applied binwise. Common choices are shot and offset binning. Several authors have recently explored formation of image gathers using diffraction sum (“Kirchhoff”) operators which image events at selected scattering angles (?; ?; ?). We shall refer to this imaging method as common scattering angle Kirchhoff migration.

Strong lateral velocity variation (“complex structure”) complicates both the theory and the practice of prestack depth migration. Lateral velocity variation induces mul-

pathing, i.e. the appearance of multiple ray paths and arrival times connecting source and receiver locations with scattering points. Imaging methods successful in models with mild lateral velocity variation may fail in the presence of multipathing. For example, prestack Kirchhoff migration with first arrivals does not always produce accurate (stacked) images in complex structure (7; 9). A number of authors have explored Kirchhoff migration with most energetic, as opposed to earliest, arrivals (8). The examples presented in (9) suggest that even most energetic arrivals may not be sufficient to produce high quality images: in some cases, all arrivals carrying significant energy may be required. Recent theoretical work (9) is consistent with this suggestion.

The purpose of this paper is to demonstrate that multipathing generally leads to inaccurate unstacked image volumes, containing spurious coherent events unrelated to actual reflectors. We shall call these spurious events kinematic artifacts, to emphasize that their origin is fundamentally different from that of other coherent image noises, such as diffractions from data truncations and unsuppressed multiple reflections. All common binning strategies, and all binwise prestack migration methods, produce kinematic artifacts in complex structure. As a result, the semblance principle fails for such prestack migration methods in the presence of strong lateral velocity variation: image gathers may not be flat, even when the velocity model closely approximates the actual propagation velocity, and all arrivals are used in the migration process.

The failure of the semblance principle is a straightforward consequence of the existence of multiple ray paths connecting reflection points with source and receiver locations. Independent migration of data bins does not give the imaging method access to event slowness in complementary, out-of-bin directions, and therefore permits imaging along several distinct (incident-reflected) ray pairs corresponding to a within-bin event. Thus energy arriving in the data along one ray pair may be imaged at the reflection point of another ray pair, giving rise to a kinematic artifact.

Claerbout has cited this phenomenon to explain the failure of the exploding reflector model to account properly for all events in zero-offset sections when the velocity model is strongly refracting (9). In the same way, events in a shot profile determine the receiver component of slowness (i.e. rate of change of event arrival time with receiver position), but not the source component, which in principle permits a single event to be imaged along several ray pairs. Nolan demonstrated that this could actually occur, using simple synthetic examples (9; 9). While Nolan used two-way reverse time finite difference migration to illustrate his conclusions, they apply equally well to Kirchhoff shot profile migration using all arrivals, or to shot profile migration using depth extrapolation. When the velocity is correct, the artifacts move out with bin parameter, whereas the correct image components do not: this fact accounts for the disappearance of the artifacts in the final stacked image (9). However image artifacts are present with strength equal to (or even sometimes greater than) that of correct image components in the prestack image volume. Their presence renders the image gathers strongly dependent on shot position (non-flat), even with precisely correct velocity.

We will extend Nolan’s result by demonstrating that kinematic artifacts occur in
prestack image volumes produced by common offset and common scattering angle Kirchhoff migration. In particular, contrary to the assertion in (?), image gathers produced using common scattering angle Kirchhoff migration are not in general flat, even when the velocity is correct. Therefore, Kirchhoff migration in the angle domain does not appear to be categorically superior to Kirchhoff (or other binwise) migration in the offset or shot domains as a basis for velocity analysis.

We will frame our discussion in terms of Kirchhoff migration, because the physics of artifact generation are most evident in the structure of Kirchhoff imaging algorithms and because the version of angle domain imaging which suffers from artifacts is usually formulated as a diffraction sum (and indeed is difficult to formulate in any other way). However the reader should be aware that any kinematically equivalent technique will yield the same results. For example, reverse time shot profile migration and Kirchhoff shot profile migration are equally prone to kinematic artifacts in complex structure. It is image formation from individual bins which is responsible for artifact generation, not any particular method of image computation.

The next section explains the kinematics of multipathing-induced image artifacts, with details spelled out for both common offset and common scattering angle Kirchhoff migration (?; ?). The following section presents two synthetic examples illustrating the generation of artifacts and the failure of the semblance principle. An acoustic lens model with flat underlying reflector, very similar to that used in (?), is simple enough that the rays pairs of both correct reflectors and artifacts are easily identifiable. The second example is due to (?), and consists of a smoothed version of the Marmousi velocity model (?) with a flat reflector. Recognition of kinematic artifacts is more difficult in this more complex model, but they are present nonetheless.

We end with a discussion of the implications of our results for velocity analysis. In particular, we contrast the properties of binwise prestack migration established here with those of a prestack migration method not based on independent data bin imaging, namely Claerbout's “survey sinking” migration (?). Recent theoretical work (?) has shown that prestack image volumes generated by survey sinking do not exhibit artifacts, and that the focussing characteristic of correct velocity for this type of migration is not affected by strong lateral velocity variation. This comparison suggests some directions for further research.

Two appendices collect mathematical and computational details.

THE KINEMATICS OF ARTIFACTS

Given a velocity model, a (potential) reflection point \( x \) is connected to a source position \( s \) by one or more branches of (one-way) traveltime, and similarly to a receiver position \( r \) by one or more branches. The two-way time therefore is indexed on both source and receiver traveltime branches: we write \( T^{(k,j)}(x, s, r) \) for the two-way time which is the sum of the \( i \)th branch from source \( s \) to \( x \) and the \( j \)th branch from \( x \) to receiver \( r \).

We do not assume complete or areal coverage, except when otherwise stated, that is, \( s \) and \( r \) do not necessarily sample areas. The in fact these variables really signify parameter
vectors which determine source and receiver positions, not necessarily the position vectors themselves. For example, for marine streamer geometry it is natural to take for \( s \) a two-
vector (source-x and source-y), and for \( r \) the offset. Source-receiver azimuth, and therefore receiver position, is then a function of \( s \) and \( r \).

Kirchhoff or diffraction sum migration places at an image point \( x \) the sum over sources \( s \), receivers \( r \), and traveltine branches \((i,j)\) of the data \( d(r,s,t) \) for \( t = T^{(i,j)}(x,s,r) \), plus possibly some filtering and scaling by amplitudes. When many branches of traveltine exist, the relative phases of the data sums over the branches must be adjusted by application of powers of the Hilbert transform. Also so called true amplitude migration, or migration-inversion, can be produced by properly chosing amplitudes. We have relegated
the details of these refinements to Appendix A. For the moment, simply write for the image amplitude

\[
\begin{align*}
    f_{\text{stack}}(x) &= \sum_{(s,r)} \sum_{(i,j)} (...) d(s,r,T^{(i,j)}(x,s,r))
\end{align*}
\]

in which (...) represents amplitudes, filters, and other operators which do not affect the presence or absence of events. The subscript emphasizes that \( f_{\text{stack}}(x) \) is the stack of the migrated data volume, which includes contributions from all traces.

An event is characterized by an identifiable arrival time function \( T_{\text{data}}(s,r) \) of source
position \( s \) and receiver position \( r \). We presume throughout our discussion that sampling in \( s \) and \( r \) is sufficiently dense that the source and receiver slownesses of the event

\[
\begin{align*}
    p_s &= \frac{\partial T_{\text{data}}}{\partial s},
    p_r &= \frac{\partial T_{\text{data}}}{\partial r}
\end{align*}
\]

are accurately determined. The event contributes significant image energy at \( x \) if one or more of the diffraction surfaces \( t = T^{(i,j)}(x,s,r) \) is tangent to the event surface \( t = T_{\text{data}}(s,r) \) at for \( s,r \) within the definition of the event: that is, \( f_{\text{stack}}(x) \) gets a contribution from the event if

\[
\begin{align*}
    T^{(i,j)} &= T_{\text{data}},
    \frac{\partial T^{(i,j)}}{\partial s} &= p_s, 
    \frac{\partial T^{(i,j)}}{\partial r} &= p_r
\end{align*}
\]

[I NEED A GOOD REFERENCE FOR THIS OTHER THAN RAKESH] Conversely, if a reflector exists at \( x \), then the reflector contributes energy only to events for which equations (2) hold. See Figure 1. We will call equations (2) the imaging equations, as they determine the relation between reflector and event locations.

The kinematic artifacts whose existence is the major claim of this paper arise through interaction of two traveltine branches, say indexed by \((i,j)\) and \((i',j')\), at different image points. Suppose that energy enters the data from a reflector at \( x \) along the incident-reflected ray pair for branch \((i,j)\), i.e. equations (2) hold for \( x,s,r,i,j \). Now suppose that

equations (2) also hold for another branch of the traveltine, with different indices \((i',j')\),

at another image point \( x' \), for the same event, i.e. at the same values of \( s,r,t,p_s,p_r \). Then the Kirchhoff migration operator (equation (1)) produces image energy at \( x' \), whether a
reflector actually exists at that location or not. That is, energy arriving in the data due to one ray pair is migrated along another. The result is a kinematic image artifact.

Kinematic artifacts do not occur in general for areal coverage. Idealizing slightly, suppose that \( s \) and \( r \) are coordinates in a plane (or on a line, for imaging based on a 2D Earth model) containing all source and receiver positions, and that \( s \) and \( r \) densely sample regions in this plane. Then \( p_s \) is a 2-vector, representing two of three components of a ray slowness vector, and determines the takeoff velocity vector of the ray connecting \( s \) with \( x \), from ray theory, hence the ray itself. Similarly \( p_r \) determines the ray connecting \( r \) with \( x \). So long as these rays intersect at only one point \( (x) \) with total time \( t = T_{\text{data}}(s, r) \), no other branch of the traveltime can produce a part of the diffraction surface tangent to the event surface at \((s, r, T_{\text{data}}(s, r))\), so necessarily \( i' = i, j' = j \), and \( x' = x \). The condition that the total time determine the reflection point is the Traveltime Injectivity Condition ("TIC") of (?), who gave a rigorous proof that artifacts do not exist in the stacked image for areal coverage (or linear coverage, for 2D) provided that TIC is assumed. While it is possible to construct velocity models and areal coverage geometries that violate the TIC, it is satisfied in many common imaging situations, for instance if incident and reflected rays to not turn horizontal. We will tacitly assume that TIC applies to the imaging problem with areal source and receiver coverage throughout our discussion.

When coverage is not areal and multipathing occurs, kinematic artifacts are the rule, rather than the exception. The example that concerns us here is the imaging of an individual data bin. We will treat two cases explicitly, both in 2D, which will be illustrated in the next section. In both cases 3D generalizations are clear; generation of artifacts is if anything easier for the analogous 3D imaging situations.

In both cases \( s \) and \( r \) are coordinates on a line. Migration of the common offset bin with half-offset \( h \) is given by

\[
f_{\text{offset}}(x, h) = \sum_s \sum_{(i,j)} (...)d(s, s+2h, T^{(i,j)}(x, s, s+2h))
\]  

An event in an offset bin determines only the midpoint slowness \( p_m = p_r + p_s \); it does not determine the offset slowness \( p_h = p_r - p_s \), as the offset moveout is not available. Therefore the correct imaging equations for a single offset bin are

\[
T^{(i,j)} = T_{\text{data}}, \quad \frac{\partial T^{(i,j)}}{\partial s} + \frac{\partial T^{(i,j)}}{\partial r} = \frac{\partial T^{(i,j)}}{\partial m} = p_m
\]  

\( m \) being the midpoint \( m = (s + r)/2 \).

Compared to equations (2), equations (4) have lost an entire equation: the offset component \( p_h \) of event moveout does not constrain the reflection point. So it is perhaps not surprising equations (4) have in general many more solutions. In particular, multipathing generally induces kinematic artifacts in offset image bins, as described above. The paper (?) gave a simple example of an artifact at zero offset, while (?) showed that such artifacts exist at all offsets, also at the purely kinematic level (map migration). The next section shows explicit Kirchhoff migrations corresponding to the kinematics of (?).
If you sum the right hand side of equation (??) over half offset $h$, you obtain the right hand side of equation (??). Since the stacked image has no artifacts, as we have argued, stacking must remove those present in the offset bins - that is, the artifacts must move out within the offset CIGs, whereas the correct image components do not. The examples of the next section illustrate this property of kinematic artifacts.

The second example, common scattering angle migration, is a bit more involved. Reflector dip $\nu$ and scattering (opening) angle $\theta$ determine (in 2D) an incident - reflected ray pair (see Figure 1). Thus we can view $s$ and $r$, as well as $t$, as functions of $x$, $\theta$, and $\nu$. The common scattering angle Kirchhoff migration operator is

$$f_{\text{angle}}(x, \theta) = \sum_{\nu}(...)d(s(x, \theta, \nu), r(x, \theta, \nu), T(x, \theta, \nu))$$

(see (??) NEED MORE REFS HERE). Note that since $x$, $\theta$, $\nu$ determine the scattering ray pair completely, the summation over traveltime branches is already implicit in the dependence on these variables, so that we do not need to supply the traveltime function with branch indices.

It is important to understand that the imaging method (5) which we call common scattering angle Kirchhoff migration, is not equivalent, even kinematically, to the “wave equation angle domain migration” introduced in (??) [MORE REFS]. We will have a bit more to say about the latter algorithm in the concluding section.

It is not so easy to envision the operator defined in equation (??) as defining the restriction of the operator defined in equation (??) to a data bin, but in fact that is precisely its identity. The bin must be described in the phase space of the data: it consists of those event elements which are tangent to the constant scattering angle diffraction surface, parametrized by $\nu$.

The imaging equations which express this tangency are

$$T(x, \theta, \nu) = T_{\text{data}}(s(x, \theta, \nu), r(x, \theta, \nu)), \quad \frac{\partial T}{\partial \nu}(x, \theta, \nu) = p_s \frac{\partial s}{\partial \nu}(x, \theta, \nu)$$

(6)

Once again, the system (6) has one fewer equation than does the system (2), so it is not surprising that it has many more solutions in general.

Appendix A describes a general formulation of binwise Kirchhoff imaging, which treats all binning schemes, including the two just described, in a unified way.

**EXAMPLES**

In this section we present two 2D examples which illustrated the formation of kinematic artifacts in common offset and common scattering angle prestack migration. The first model contains a horizontal reflector below a low velocity lens, and closely resemble the model used in (??), also (??). The lens is sufficiently refracting that multipathing occurs. The second example is based on a slight smoothing of the Marmousi velocity model (??), which is well known to produce multipathing. Reflectivity is again supplied by a flat
reflector, at the level of the “target” structure in the original Marmousi model. This “Marmousi plus flat reflector” model was introduced by (?)).

We demonstrate the presence of image artifacts in two ways. By solving the imaging equations (i.e. equations (??) or (??)) we determine rays that lead to artifacts and predict the positions of both correctly and incorrectly located reflectors in (offset and angle) bin images and common image point gathers. Second we migrate synthetic data using the numerical implementation of Kirchhoff prestack depth migration described in the Appendix A. By combining the results we can clearly distinguish between kinematic artifacts and other sources of “noise” that may be present in the image. The results show that artifacts are present and are energetically of the same order of magnitude as the correctly positioned reflectors. There is strong agreement between kinematic predictions of reflector locations and apparent reflectors in the migrated image volume.

Clearly a field data example illustrating the appearance of kinematic artifacts would be most interesting. The theory and examples presented here and elsewhere leave little doubt that artifacts occur in imaging near and under gas chimneys, salt flanks, and other highly refracting structures. However the purpose of examples in the context of this paper is to verify the appearance in migrated volumes of image components predicted by the theory. While it should be possible to identify artifacts in field data image bins, as is done here with synthetics, using any reasonable velocity model, illustration of our key contention - that image gathers are not flat for “correct” velocity due to multiple images of primary reflections - requires that both a “correct” velocity model and primary reflection energy be identified first. This is a nontrivial task precisely in those situations of strong lateral velocity variation that give rise to the phenomenon under study. Therefore we have limited ourselves in this exposition to synthetic examples, where the “correct” velocity is under our control.

**The Lens Model**

The first velocity model contains a low velocity Gaussian lens centered 1 km below the origin of the coordinate system (on the recording surface $x_2 = 0$). The velocity is given explicitly by and is given explicitly by

\[
c(x_1, x_2) = 1 - 0.4 e^{-9(x_1^2+(x_2-1)^2)}
\]

in km/s. We locate horizontal reflector at depth $x_2 = 2$ km. Velocity model and reflector are displayed in Figure 2. Some of the rays and wave fronts produced by this model are displayed in Figure 3. A triplication occurs below the lens, leading to three travel-time functions, numbered 1 to 3 as indicated in the figure.

We generated a synthetic dataset for this model using a finite difference wave equation solver of order 2 in time and 4 in space. To simulate a reflector, we introduced a 15% jump in the velocity profile at $x_2 = 2$ km. The geometry is such that no multiple reflections are recorded. The sampling was adequate in all directions (ten gridpoints per wavelength), and the time sample rate high enough, to yield at most 2% error in phase velocity and no visible grid dispersion (?). The source was a $(4, 10, 20, 40)$ Hz zero phase bandpass
filter. The data consists of 401 shot records for $s$ ranging from from $-2$ to $2$ km with shot spacing $0.01$ km. For each shot the response was recorded at 401 receivers with the same coverage and sample rate as the shots. The recorded data simply sampled the simulated pressure field at a depth of $10$ m below the surface.

No absorbing boundary conditions were applied, but the domain was chosen so large that reflections from the boundary arrived significantly later than reflections from the horizontal reflector, with different moveout, so that boundary reflections have no significant effect on the migrated image volume. Figure 4 displays a shot record for $s = 0.5$.

A numerical implementation of Kirchhoff prestack depth migration for the offset and angle domains (equations (3) and (5) respectively) produced offset- and angle-dependent image volumes $f_{\text{offset}}(x, h)$ and $f_{\text{angle}}(x, \theta)$ respectively. The stacked image ($f_{\text{stack}}(x)$, equation (1)) amounts to the summation of $f_{\text{offset}}(x, h)$ over $h$, or $f_{\text{angle}}(x, \theta)$ over $\theta$; except for discretization effects, the results should be the same. Figure 5 shows the stacked image: the reflector is indeed recovered at the correct position, and no artifacts appear, as predicted by (?).

The numerical implementation of Kirchhoff migration used in these examples is described in Appendix A.

**Common offset**

To determine the position and slownesses of an event in the data, we trace source and receiver rays from the reflection point in the subsurface, determine where they intersect the acquisition plane, given in this example by $x_2 = 0.01$ km, and calculate $s, r, t = T_{\text{data}}(s, r), p_a,$ and $p_r$. The complete set of reflectors, correct and artifact, corresponding to this event are obtained by solving the imaging equations (4).

Solving these equations involves a combination of ray tracing and root finding. Appendix B describes the solution method in detail.

Figure 6 displays the results of this analysis for a reflecting element at $x = (0.303, 2)$ km, with opening angle $28.05$ degrees (chosen so that the offset was equal to $1$ km). Migration forms an image at three positions, corresponding to the three ray pairs shown in the figure. This prediction is completely kinematic; to see whether significant energy is imaged at these positions we overlay the constant offset image for offset $h = 1$ km, with the ray pairs in Figure 7. Indeed roughly equivalent image amplitude occurs at all three positions, with apparent reflector orientation as predicted by the kinematic computation.

We have similarly analyzed the kinematics of offset common image gathers (“CIGs”), and thus predicted the kinematics of events in the offset CIG for $\bar{x}_1 = 0.3$ km. These kinematic predictions are the colored lines in Figure 8, the different colors corresponding to different combinations of travel time functions (i.e. index pairs $(i, j)$). The kinematic predictions are overlain on the graylevel plot of the CIG produced by prestack depth migration. All kinematic predictions coincide with events in the migrated data.
Common scattering angle

Kinematic predictions of image components, both correct and artifact, follows from an analysis similar to that used in the common offset case. Algorithmic details are explained in Appendix B.

Figure 9 shows the ray pairs corresponding to correct image and artifacts for data due to reflection at (0.3, 2) km, opening angle 40 degrees and for reflection at (0, 2) km (below the lens) opening angle 10 degrees. In addition to the ray pairs, we display the isochrons (the solutions in position $x$ of $t = T^{(i,j)}(x, r, s)$ for the various branches $(i, j)$). The various images of a given event, correct and artifact, occur at different opening angles, therefore this picture cannot be compared with a single constant angle image. A constant angle image for angle 30 degrees is given in Figure 10.

Figure 11 shows a greyscale plot of the angle CIG for $x_1 = 0.3$ km, with the predicted events superimposed (colored lines). Again all the predicted artifacts can be observed in the synthetic data example and there is strong agreement between the kinematic and synthetic data plots. Angle CIG’s for $x_1 = 0$ km and $x_1 = 0.6$ km are given in Figure 12. Again artifacts are present and of size of the same order of magnitude as the correct image. As can be expected the artifact moves to larger angles for increasing $x_1$.

**DISCUSSION**

The preceding examples establish that kinematic artifacts, i.e. coherent reflectivity not corresponding to actual reflectors, can exist in prestack image volumes produced by binwise migration, given strong lateral velocity variation and concomitant multipathing. Such artifacts exist in particular for both common offset and common angle Kirchhoff prestack depth migration, and we have given explicit, clear-cut 2D examples of this phenomenon. In particular, formulation of Kirchhoff migration in the common angle domain does not suppress imaging artifacts, contrary to assertions in the literature (?).

We have focused our attention on Kirchhoff migration, but in fact the same conclusions hold for any binwise migration method including contributions from all arrivals, such as reverse time or depth extrapolation shot profile migration. For example, Nolan has exhibited kinematic artifacts in reverse time common source migration image volumes (?; ?). The examples in (?) illustrate the necessity of including all arrivals carrying significant energy to maintain image quality in the presence of multipathing; the relevant theory also suggests this requirement (?; ?). However it is precisely the interaction of various arrival branches that create kinematic artifacts.

Perhaps the most striking conclusion to be drawn from our analysis is that image gathers produced by binwise migration are not in general flat in the presence of strong refraction, even when the velocity model is precisely correct, because of the production of kinematic artifacts. Flattening image gathers is the underlying mechanism of practical velocity analysis. Gathers may be contaminated by many types of coherent noise. However kinematic artifacts may be particularly difficult to distinguish from events which should be flattened. Artifacts can move out in a wide variety of styles, as even our simple examples
illustrate. Artifacts bear no particular space-time relation to the actual reflectors which they spoof: unlike multiple reflections, they can appear either earlier or later than the source reflector in an image gather, and are more or less equally energetic. For all of these reasons, processing designed to suppress multiple reflection energy or edge effects will not attenuate kinematic artifacts, which will be present whenever primary reflections are imaged at all. Thus the presence of kinematic artifacts must complicate migration velocity analysis in complex structure. The complication could easily be fatal for automated velocity analysis algorithms, such as differential semblance optimization [REFERENCE].

Very recently, evidence has emerged that “survey-sinking” or “double square root” migration, introduced by Claerbout (?) does not generate kinematic artifacts (?). The same is true of the wave equation common angle migration techniques (?; ?), which are variants on survey-sinking. While these algorithms were introduced as applications of wavefield depth extrapolation, the fundamental reason for the absence of artifacts has nothing to do with depth extrapolation per se. The essential feature of these algorithms, responsible for the absence of kinematic artifacts, is that they do not migrate individual image bins: each output point in the prestack image volume depends (in principle) on the entire data volume, in such a way that migration of energy along the wrong ray pair is simply impossible.

The difference is perhaps best explained by comparing prestack Kirchhoff common offset migration (equation (3)) with a diffraction sum expression for survey-sinking migration. [This comparison also emphasizes our point that depth extrapolation is not the algorithm feature which guarantees artifact avoidance.] Survey sinking introduces a (vector) parameter of the image volume, generally called (half) offset and denoted by \( h \). The name is natural in view of Claerbout’s motivation of survey sinking (?), but in fact this parameter cannot be identified with the source-receiver offset of the survey geometry - for example, it does not need to be horizontally oriented [REF TO BIONDO’S SEG PAPER]. Introduce the survey sinking two way time branches \( T^{(i,j)}(x, h, s, r) \) - the sum of the \( i \)th branch of the one-way time from \( s \) to \( x - h \) and the \( j \)th branch of the one-way time from \( x + h \) to \( r \). Then the Kirchhoff representation of survey-sinking migration is

\[
 f_{ss}(x, h) = \sum_{s,r} \sum_{i,j} \ldots d(s, r, T^{(i,j)}(x, h, s, r)) \tag{8}
\]

Claerbout’s imaging condition is: extract the zero-offset section. Clearly at \( h = 0 \) equation (8) becomes identical to equation (1) so that \( f_{ss}(x, 0) = f_{stack}(x) \). The nonzero offset output also involves the entire data set: this is not a binwise migration algorithm, and the algorithm accesses full events for each \( h \), unrestricted by data binning. Therefore full slowness information is available at each \( h \).

The paper (?) contains a demonstration that equation (8) actually yields the same migrated image as survey sinking via the double square root equation as defined in (?), and also that this form of prestack migration produces an image volume uncontaminated by kinematic artifacts whenever the same is true of the stacked image. Wave equation angle domain migration is essentially survey sinking migration followed by a Radon transform in offset and time (?) or depth (?), so these methods are also artifact-free.
When the migration velocity is kinematically accurate, the output of survey sinking migration is concentrated or focussed at offset zero. The result of (?) shows that focussing occurs at zero offset even in the presence of severe lateral velocity variation and multipathing. It has been suggested that the focussing property of survey sinking migration could be used as the basis of a velocity analysis method, i.e. as another form of the semblance principle (?). [REFERENCE: SHERWOOD ARTICLE FROM SEG MIGRATION VOLUME - ALSO DOES THIS HAVE SOMETHING TO DO WITH FOCUSING ANALYSIS A LA FAYE AND JEANNOT 1986 SEG? I WILL TRACK THIS DOWN]

Our results suggest that this velocity analysis concept may be particularly appropriate for accurate imaging in complex structure.
REFERENCES

APPENDIX A

In this appendix we present a unified theory of prestack Kirchhoff migration, applicable to all domains (shot, offset, angle,...). This formulation facilitates a uniform analysis of artifact generation, via conditions which we call the imaging equations. We also describe the particular choices of discretization used in our computational implementation of Kirchhoff migration.

Migration Operators

A reflecting pair of geometrical optics rays can be parametrized by the reflection point \( x \) in the subsurface and the takeoff angles \((\beta, \alpha)\) for the source and receiver rays. For 2D modeling, \( x = (x_1, x_2) \), \( x_2 \) denoting depth, and \( \beta, \alpha \) are ordinary angles. For 3D modeling, \( x = (x_1, x_2, x_3) \), \( x_3 \) denoting depth, and \( \beta, \alpha \) are solid angles.

We assume for convenience that the source and receiver positions are located on a constant-depth acquisition plane, say \( x_2 = 0 \) (2D) or \( x_3 = 0 \) (3D). The analysis remains valid if these positions lie on non-planar surfaces instead, and if sources and receivers lie at different depths. The data \((x, \beta, \alpha)\) determines the intersection point \( s(x, \beta) \) of the source ray with the acquisition plane together with the corresponding travel time \( t_s(x, \beta) \), and similarly for the receiver \( r(x, \alpha), t_r(x, \alpha) \), see Figure 1.

The map \((x, \alpha) \mapsto (x, s(x, \alpha))\) in general maps several angles \( \alpha \) to the same source (multipathing). Therefore there are multiple inverse functions mapping \((x, s)\) to the takeoff angle, which we will denote by \( \alpha^{(i)}(x, s) \). Each inverse function is defined for \((x, s)\) in a set \( D^{(i)} \) and corresponds to a branch one-way travel time, denoted \( T_1^{(i)}(x, s) \), defined for \((x, s) \in D^{(i)} \).

Since the traveltime branches are generally only local, not global, it will be necessary to cut off or mute the data to be summed over the resulting local diffraction surfaces. Define a smooth cutoff (mute) function \( A_1^{(i)}(x, s) \) on \( D^{(i)} \), identically equal to one sufficiently far from the boundary of \( D^{(i)} \), and identically zero near the boundary.

The two way travel time \( T^{(i,j)}(x, s, r) \) is

\[
T^{(i,j)}(x, s, r) = T_1^{(i)}(x, s) + T_1^{(j)}(x, r) \tag{9}
\]

In two dimensions we can define the scattering angle \( \theta^{(i,j)}(x, s, r) \) by

\[
\theta^{(i,j)}(x, s, r) = \alpha^{(j)}(x, r) - \alpha^{(i)}(x, s) \tag{10}
\]

For a definition of scattering angle - azimuth appropriate for three dimensions, see (?). These functions are defined for \((x, s, r)\) in a domain \( D^{(i,j)} \) consisting of points \((x, s, r)\) with \((x, s) \in D^{(i)} \) and \((x, r) \in D^{(j)} \).

A cutoff function for the domain \( D^{(i,j)} \) is given by

\[
A^{(i,j)}(x, s, r) = A_1^{(i)}(x, s) A_1^{(j)}(x, r) \tag{11}
\]
For the purposes of this paper, the Kirchhoff imaging formula is

\[
f(x) = \sum_{i,j} \int ds \, dr \, A^{(i,j)}(x, r, s)(H^{n-1-\sigma(i)}-\delta^{(j)})d(r, s, T^{(i,j)}(x, r, s)).
\]

(12)

Here \( n = 2 \) in 2D, \( n = 3 \) in 3D. The output is a single image function \( f(x) \) of position - that is, this formula implements migration plus postmigration stack. The operator \( H \) appearing in the integrand is the Hilbert transform with respect to time, and \( \sigma^{(i)} \) is the KMAH index of the \( i \)th traveltime branch, to account for the phase shift that occurs when the rays go through a caustic.

As mentioned above, (12) explained that this formula produces a correct image, with reflectors in the right places and not elsewhere, provided that the so-called Traveltime Injectivity Condition (“TIC”) is satisfied. This condition is satisfied for both examples presented in the paper, and indeed our theoretical development assumes it. See (12) for examples in which TIC fails, (12) for an extension of the TIC concept to general acquisition geometries, and (12) for a less restrictive condition which also assures correct imaging.

Many variants of this formula have been proposed, either restricting the traveltime branches appearing in the sum or adding amplitude factors to attempt to achieve “true” reflection amplitude in the output image. As we have noted in the introduction, neglect of traveltime branches generally degrades the image (12, 12). Variants taking into account all traveltime branches are kinematically equivalent to (12), i.e. produce reflectors with the same locations and orientations.

Various Kirchhoff prestack migration formulas follow from (12) by restricting the integral over \((s, r)\) to a constant value of the image (or bin or gather) parameter. The latter can be viewed as a function \( e(x, \alpha, \beta) \), and hence as a (possibly) multivalued function \( e^{(i,j)}(x, s, r) \). Three important examples are \( e^{(i,j)}(x, s, r) = s \) (common source), \( e^{(i,j)}(x, s, r) = r-s \) (common offset), and \( e^{(i,j)}(x, s, r) = \theta^{(i,j)}(x, s, r) \) (common scattering angle). Restricting the integral (12) by inserting a \( \delta \)-function of \( e \) we obtain

\[
f(x, e) = \sum_{i,j} \int ds \, dr \, A^{(i,j)}(x, s, r)
\times \delta(e - e^{(i,j)}(x, s, r))(H^{n-1-\sigma^{(i)}-\sigma^{(j)})d(s, r, T^{(i,j)}(x, s, r)),
\]

That is, the output is a function \( f(x, e) \) of position \( x \) and bin parameter \( e \). A further integration over \( e \) produces \( f(x) \) (output of (12)). So \( f(x, e) \) is the unstacked image volume, expressed in a generic way that applies to all of the binning schemes mentioned above.

**Imaging equations**

Suppose a reflector at a subsurface point \( x \) leads to an event (wave front) at a position in the data given by \((s, r, t_a + t_r)\), with slowness \((p_a, p_r)\). In (12) equations have been derived that describe the points \((\tilde{x}, \tilde{e})\) in the image volume (i.e. the output \( f(x, e) \) in (13)) at
which this event leads to an apparent reflector. The apparent reflector coordinates \((\bar{x}, \bar{e})\) correspond one-to-one with the solutions \((\bar{x}, p_e)\) of the equations

\[
T^{(i,j)}(\bar{x}, s, r) = t_s + t_r,
\]

\[-\langle p_e, \frac{\partial T^{(i,j)}}{\partial s}(\bar{x}, s, r) \rangle + \frac{\partial T^{(i,j)}}{\partial s}(\bar{x}, s, r) = p_b,\]

\[-\langle p_e, \frac{\partial T^{(i,j)}}{\partial r}(\bar{x}, s, r) \rangle + \frac{\partial T^{(i,j)}}{\partial r}(\bar{x}, s, r) = p_r. \tag{14}\]

Here \(p_e\) is equal to the \(e\)-wave vector divided by \(-\tau\) (the \(e\)-slowness or moveout). The bin parameter (angle or offset) of the wave front is given by \(\bar{e} = a^{(i,j)}(\bar{x}, s, r)\). Together, (14) consists of \(2n - 1\) equations for \(2n - 1\) unknowns, with no obvious dependencies. [Again, \(n\) denotes space dimension, \(n = 2\) for 2D imaging, \(n = 3\) for 3D imaging.] So one might guess that the solutions are stable, and indeed this is generally the case. As explained in (?) one set of solutions corresponds to the correct image, with \((i,j)\) corresponding to the raypaths of the data \((s, r, p_b, p_r, t_s + t_r)\), and \(\bar{x} = x, p_e = 0\) (zero \(e\) move-out). In addition there may be other sets of solutions - the artifacts of the title - that must satisfy \(p_e \neq 0\) in view of TIC (see (?)).

If \(e = \text{offset}\), the equations (14) simplify to \(n\) equations for \(\bar{x}\) and \(p_e = \bar{p}_b + \bar{p}_r\):

\[
T^{(i,j)}(\bar{x}, s, r) = t_s + t_r,
\]

\[\bar{p}_b + \bar{p}_r = p_b + p_r. \tag{15}\]

Appendix B describes the numerical methods used to solve the equations (14) in the offset and angle cases.

**Numerical implementation of migration formulas**

This section describes a numerical implementation of (13). The authors make no pretense that this implementation is optimal in any way, other than that it appears to approximate (13) with sufficient accuracy to illustrate the contentions in this paper.

Numerical implementation of (13) requires discrete approximations to the one-way travel-time function, cutoff function, angle function \(T_1^{(i)}(x, s), A_1^{(i)}(x, s), \alpha^{(i)}(x, s)\) for all values of the branch index \(i\), and the integration in (13). The two-way quantities can then be calculated from (9), (10), (11).

Suppose data is given on a regular grid of \((s, r, t)\) values with grid intervals (or interval vectors, for 3D problems) \(\Delta s, \Delta r\) and \(\Delta t\), possibly after binning from irregularly sampled \(s\) and \(r\). Image location and bin parameter occupy a regular grid of \((x, e)\) values. Gridded values of these coordinates will be denoted by \(\hat{s}, \hat{r}, \hat{t}, \hat{x}, \hat{e}\) respectively.

In our implementation of (13), we used numerical ray tracing to compute approximations to \(T_1^{(i)}(\hat{x}, \hat{s}), A_1^{(i)}(\hat{x}, \hat{s}), \alpha^{(i)}(\hat{x}, \hat{s})\) and the KMAH indices \(\sigma^{(i)}\), keeping for each pair \((\hat{x}, \hat{s})\) up to three arrivals. This tactic was adequate for the examples presented below; the task of writing a general purpose code along these lines must be formidable.

Integrations over \(s, r\) are approximated by the trapezoidal rule. For time \(t\) not in the grid, the (possibly) Hilbert transformed data is approximated by linear interpolation. The
\( \delta \)-function in \( e \) is approximated by adjoint interpolation. In the 2D imaging case, \( e \) is a scalar variable, sampled at interval \( \Delta e \). Let \( e_{\text{int}} \) denote integer part of \( e^{(i,j)}(\hat{x}, \hat{s}, \hat{r})/\Delta e \), and \( e_{\text{frac}} = e^{(i,j)}(\hat{x}, \hat{s}, \hat{r})/\Delta e - e_{\text{int}} \). In this notation a discrete approximation \( \hat{\delta} \) to \( \delta(e - e^{(i,j)}(\hat{x}, \hat{s}, \hat{r})) \) is given by

\[
\hat{\delta}(\hat{e}, \hat{x}, \hat{s}, \hat{r}) := \frac{(1 - e_{\text{frac}})\delta_K(\hat{e}, e_{\text{int}}) + e_{\text{frac}}\delta_K(\hat{e}, e_{\text{int}} + 1)}{\Delta e}
\]

where \( \delta_K \) is the Kronecker \( \delta \) on the \( \Delta e \) lattice. A similar approximation is possible for the 3D case.

With these approximations, the discrete version of (13) is

\[
\hat{f}(\hat{x}, \hat{e}) = \Delta s \Delta r \sum_{i,j} \sum_{\hat{s}, \hat{r}} A^{(i,j)}(\hat{x}, \hat{s}, \hat{r}) \hat{\delta}(\hat{e}, \hat{x}, \hat{s}, \hat{r})(H^{n-1-\sigma(i)-\sigma(j)}) \hat{d}(\hat{s}, \hat{r}, T^{(i,j)}(\hat{x}, \hat{s}, \hat{r})).
\]

The implementation used below consisted of two stages. The first stage employed numerical ODE solvers and interpolation routines in a general purpose mathematical software package (Mathematica\textsuperscript{TM}) to compute the gridded travel time data \( T^{(i)}(\hat{x}, \hat{s}) \), \( A_1^{(i)}(\hat{x}, \hat{s}), \alpha^{(i)}(\hat{x}, \hat{s}), \sigma^{(i)} \) and stored the results to disk files. The second stage consisted of a program, written in C, which read the travel time data and the input seismograms from disk, and evaluated the sum (17), storing its results to disk as well.

For the lens model evaluations of (17), the one-way travel times \( T_1^{(i)}(x, s) \), a cutoff \( A^{(i)}(x, s) \) and the one-way angle function \( \alpha^{(i)}(x, s) \), \( i = 1, 2, 3 \), were computed on the domain \( (x_1, x_2, s) \in [0, 1] \times [1.5, 2.5] \times [-2, 2] \ \text{km}^3 \), with grid interval 0.01 km in all three directions. We made similar choices of discretization for the Marmousi problem.

**APPENDIX B**

This appendix gives a detailed account of the methods used to solve the imaging equations (14), for both the common offset and common angle cases.

**Common Offset**

The first equation in (15) implies that there are rays connecting \( s \) and \( r \) to the imaging point \( \bar{x} \) with total travel time equal to \( t_s + t_r \). Denote by \( \bar{p}_s \) and \( \bar{p}_r \) the horizontal slownesses of the rays at the surface. It follows that there must be \( t \) such that

\[
F(s, r, \bar{p}_s, \bar{p}_r, t) := x(s, \bar{p}_s, t_s - t) - x(r, \bar{p}_r, t_r + t) = 0.
\]

Here \( x(s, p, t) \) is the position at time \( t \) along the ray with initial conditions at the surface determined by \( s, p \).

The second equation in (15) implies that there is \( p \) such that \( \bar{p}_s = p_s - p, \bar{p}_r = p_r + p \). The image point \( \bar{x} \) is the intersection point of the rays with surface initial conditions
determined by \((s, p_s - p), (r, p_r + p)\). Therefore artifacts correspond to solutions \(t, p, p \neq 0\), to the following equations for the coordinates \(\bar{x}_1\) and \(\bar{x}_2\) of the intersection point:

\[
\mathbf{x}(s, p_s - p, t_s - t) = \mathbf{x}(r, p_r + p, t_r + t).
\]

(19)

We solve these equations using the Mathematica™ root finder. One can make use of the fact that rays carrying significant energy in this example are increasing in depth, i.e. that \(t\) is a monotone increasing function of depth along a ray, to first solve for \(t\) as a function of \(p\). Then a single equation for \(p\) remains.

Creating a kinematic common image gather amounts to finding all solutions to (15) for some fixed value of the horizontal image coordinate \(\bar{x}_1\). Since the reflector is flat and specular, true reflection locations are parametrized by horizontal position \(x_1\) and scattering angle \(\theta\). Each solution of (15) - i.e. each apparent reflector, true or artifact, in the migrated image volume - corresponds to a true reflecting position which generated the data event which it images. So we can parametrize the solutions of (15) by the true reflection position \((x_1, \theta)\) to which it corresponds. In these calculations we use the multivalued travel time database subsequently used for prestack migration.

For each pair of potential true reflection parameters \((x_1, \theta)\), we compute the surface event coordinates \(s, r, p_s, p_r, t_s + t_r\) as functions of \(x_1, \theta\). Since the horizontal coordinate of the image \(\bar{x}_1\) is prescribed, and the time is increasing with depth along both incident and reflected rays in the region of interest, the travel time equation in (15) uniquely fixes the depth coordinate \(\bar{x}_2(x_1, \theta)\). The \(p_s, p_r\) equation in (15) now determines a subset of all \((x_1, \theta)\) that contributes to the CIG, i.e. we have to find all \((x_1, \theta)\) that satisfy

\[
0 = R^{(i,j)}_{\text{offset}}(x_1, \theta) := \left( \frac{\partial T^{(i)}_1}{\partial s}(\bar{x}(x_1, \theta), s) + \frac{\partial T^{(j)}_1}{\partial r}(\bar{x}(x_1, \theta), r) \right) - (p_s(x_1, \theta) + p_r(x_1, \theta)).
\]

(20)

When at a zero \((x_1, \theta)\) of \(R^{(i,j)}_{\text{offset}}(x_1, \theta)\) the gradient \(\frac{\partial R^{(i,j)}_{\text{offset}}}{\partial (x_1, \theta)} \neq 0\), then the zero set of \(R^{(i,j)}_{\text{offset}}\) is locally a curve. In that case the zero set can be determined in a stable manner by a numerical root-finding algorithm. Our computations were based on this assumption, which was sufficient to compute the examples given below. Note that it need not be satisfied in general (see the remark at the end of the next subsection). For the value \(\bar{x}_1 = 0.3\) we computed \(R^{(i,j)}_{\text{offset}}\) for a sufficiently large array of \((x_1, \theta)\) values. We observed that in this case the gradient was nonzero at the zeroes of \(R^{(i,j)}_{\text{offset}}\), with a single exceptional point. The values of \(R^{(i,j)}_{\text{offset}}\) were displayed, allowing for the approximate determination of the zero set. The zero set was then determined precisely using a numerical root-finding algorithm. At the exceptional point, where \(R^{(i,j)}_{\text{offset}}\) and its gradient were zero, an intersection of two of the zero curves occurred. In this case we determined the curves by bisection, starting from under- and overestimates of the zero.

**Common Angle**

The analysis for common scattering angle binning follows the same pattern as for common offset binning. For each point on the reflector given by \(x_1\), and opening angle
\[ \theta \] the quantities \( s, t_s, p_s, r, t_r, p_r \) can be determined as described above. First we compute rays leading to correct image and artifacts for given values of \( s, t_s, p_s, r, t_r, p_r \). As explained in the previous section the travel time equation in (14) implies that there must be \( t \) such that (18) is satisfied. Given \( p_s, \bar{p}_s \) (the “modeling” and “imaging” values of the source slowness), there is a unique value \( p_e = \mathbf{p}_{e,s}^{(i,j)}(s, p_s, \bar{p}_s, \bar{t}_s) \) such that the second equation of (14) is satisfied. Similarly \( p_e = \mathbf{p}_{e,r}^{(i,j)}(r, p_r, \bar{p}_r, \bar{t}_r) \) satisfying the third equation can be found. The two must be the same, which leads to the equation

\[ 0 = \mathbf{p}_{e,s}^{(i,j)}(s, p_s, \bar{p}_s, t_s - t) - \mathbf{p}_{e,r}^{(i,j)}(r, p_r, \bar{p}_r, t_r + t). \]  

(21)

Equations (18) and (21) form 3 equations for the 3 variables \( \bar{p}_s, \bar{p}_r, t \) (in 2D). The position \( \bar{x} \) is given by \( \mathbf{x}(s, \bar{p}_s, t_s - t) = \mathbf{x}(r, \bar{p}_r, t_r + t) \), the angle is computed from the directions of the imaging rays at the intersection point.

The numerical rootfinding for these equations was done in two steps. If \( \xi \) is a direction (vector) with positive inner product with the velocity vectors of the rays to both source and receiver, then the inner product of \( \xi \cdot F(\ldots, t) \) is decreasing with \( t \), and the solution to \( \xi \cdot F = 0 \) is a straightforward rootfinding exercise. Then two equations remain with unknowns \( p_s, p_r \). By computing the values for an array of \( p_s, p_r \) the solutions can be found approximately. By numerical rootfinding precise solutions can then be found.

The kinematic computation of position of wave fronts in the angle CIG proceeds similarly as in the offset case. In this case, according to (21), the function \( R_{\text{angle}}^{(i,j)}(x_1, \theta) \) is replaced by

\[ R_{\text{angle}}^{(i,j)}(x_1, \theta) := \mathbf{p}_{e,s}^{(i,j)}(s, p_s, \bar{p}_s, \bar{t}_s) - \mathbf{p}_{e,r}^{(i,j)}(r, p_r, \bar{p}_r, \bar{t}_r), \]  

(22)

where \( \bar{t}_s = T_1^{(i)}(\bar{x}, s) \), \( \bar{p}_s = \frac{\partial R_{\text{angle}}^{(i)}}{\partial s}(\bar{x}, s) \) and similar for \( \bar{p}_r, \bar{t}_r \).

Figure 11 shows the results of this calculation for \( x_1 = 0.3 \), as discussed in the text. For \( x_1 = 0 \) we also tried to determine the zero set of \( R_{\text{angle}}^{(i,j)}(x_1, \theta) \). However, we observed that the gradient of \( R_{\text{angle}}^{(i,j)}(x_1, \theta) \) was close to zero and the determination of the zero set using our methods became difficult.
